Case*

P. J. is a 74-year-old man who noted enlarged lymph nodes while shaving. A T3N2M0 squamous cell cancer of the floor of his mouth is diagnosed. Combination chemotherapy with cisplatin and fluorouracil is begun. Concomitant radiotherapy is provided. Two weeks into therapy, he says his mouth is exquisitely painful, and he cannot eat or drink. Examination of his oral mucosa shows broad areas of erythematous, desquamated epithelium. Masticated food is noted between the teeth. A few areas of white plaque consistent with thrush are seen.

* This case is not on an EPEC-O Curriculum trigger tape.

Introduction

Oral mucositis is a common complication of both chemotherapy and radiation therapy. It is the dose limiting toxicity of concurrent chemotherapy and radiotherapy and of accelerated and hyperfractionated radiotherapy. From the patient's perspective, mucositis is a debilitating toxicity of therapy.

Prevalence

The overall incidence of oral mucositis is approximately 40% in patients who receive standard dose chemotherapy.¹ However, the incidence varies with the medication, doses and schedules used and occurs in up to 100% of patients undergoing high dose chemotherapy with hematopoietic stem cell transplantation.²

Prognosis

Mucositis is generally self-limiting. The prognosis is generally good if the comorbidities such as pain, decreased oral intake, fluid deficits, and dental caries are also managed. However, mucositis has an impact on overall treatment outcomes. In patients receiving hematopoietic stem cell transplantation, mucositis is associated with an increased risk of infection and additional hospital days, days of parenteral nutrition, intra-venous opioid use, and greater 100-day mortality.³ In general, the combination of neutropenia and mucositis increases the risk of infection.

Pathophysiology

Increasing understanding of the pathophysiology of mucositis reveals it to be a complex problem that is not simply a result of injury to the basal epithelial stem cells.

Oral mucositis is caused by direct injury from radiation or chemotherapy therapy, secondary infection, or graft versus host disease.

The pathobiology of mucositis is a multistage process including initiation, message generation, amplification of signaling, ulceration, and healing.⁴ The initiation phase is

characterized by both DNA and non-DNA damage in the epithelial submucosa. The initial insult with radiation or chemotherapy triggers a cascade of biological events, many of which are mediated by the generation of reactive oxygen species. During the message generation phase, a number of transcription factors are upregulated (eg, NF-KB) leading to the production of pro-inflammatory cytokines and enzymes. The tissue injury caused by these factors is accelerated and amplified through feed back loops during the third phase, signaling/amplification. These events lead to the clinical phase of concern, ulceration. The oral bacteria which colonize the ulcer's surface potentiate the injury through shed cell wall products. These products activate macrophages, stimulate cytokines, and increase the injury. The final phase, healing, occurs spontaneously and is dependent on extracellular matrix signals, which are still not well understood, and epithelial cell migration, proliferation, and differentiation.

Assessment

Mucositis is a *mucosal barrier injury, characterized clinically by oral erythema, ulceration, and pain following the use of known stomata-toxic therapy.*² The timing and location of the oral lesions help differentiate mucositis from oral infections and graft versus host disease. Oral viral infections frequently coincide with fever and are typically localized and involve keratinized mucosa of the hard palate, gingival, and dorsal tongue.⁵ Oral ulcers secondary to graft versus host disease are seen in patients who have undergone allogeneic stem cell transplantation and may develop after hematologic recovery. These ulcers are often lichenoid in character and may be associated with xerostomia.⁶ Chemotherapy induced mucositis most commonly involves the soft palate, antrum of the tongue/floor of the mouth, and buccal mucosa.⁵ Chemotherapy induced mucositis generally presents 5-7 days after treatment and resolves within 2 days to a few weeks.⁷ While chemotherapy induced mucositis tends to be acute, radiation-induced mucosal injury has a more chronic course.

Radiation therapy related mucositis is a function of the cumulative dose delivered. Mucositis is generally first seen after 15-20 Gy have been delivered to the mucosa. At about 30 Gy, ulcerative mucositis develops.⁸ Mucositis due to radiation typically lasts 6 weeks.⁹

Management

Prevention

The prevention of oral mucositis has been an important goal. Four theoretical approaches have been articulated.¹⁰

1. Reduce mucous membrane exposure to the cytotoxic agent. Oral cryotherapy is recommended for patients receiving bolus 5-FU.¹¹ Theoretically, placing ice in the mouth 5 minutes before bolus treatment with 5-FU and for 30 minutes after chemotherapy, cools

the oral cavity leading to vasoconstriction and decreased oral cavity medication exposure. Randomized trials have demonstrated a 50% reduction in 5-FU induced oral mucositis with cryotherapy.^{11,12,13} Additional studies are underway.

2. Reduce infectious and inflammatory complications. Another mechanistically-based therapy is glutamine supplementation. L-glutamine may decrease treatment-induced metabolic deficiencies and promote healing. Studies of L-glutamine oral rinses for mucositis have not shown efficacy, likely due to poor absorption when administered topically. AES-14, a proprietary vehicle which enhances mucosal uptake of L-glutamine and the amino acid, reduced the incidence of mucositis in a placebo-controlled phase 3 trial in patients at risk for mucositis secondary to anthracycline-based chemotherapy. Additional studies are underway.¹⁴ Antimicrobials are largely used for the treatment of associated or secondary infections. Iseganan, an analog of protegrin-1, has broad spectrum anti-microbial activity. Early studies suggest its use reduces mucositis, though more data are needed.¹⁵

3. Modify epithelial proliferative capabilities. Keratinocyte growth factor, a member of the fibroblast growth factor family, is an epithelial mitogen which acts through a subset of fibroblast growth factor receptors expressed predominantly on epithelial cells.^{7,16,17} Keratinocyte growth factor is upregulated after epithelial injury and plays a role in tissue repair. A double blind, randomized placebo controlled study of recombinant human keratinocyte growth factor (rHuKGF-1, palifermin) in patients undergoing high dose chemotherapy and hematopoietic stem cell transplantation demonstrated a reduction in the severity and duration of oral mucositis, improvement in quality of life, and a decrease in opioid usage and days of total parenteral nutrition in the patients who received rHuKGF-1.¹⁸ Additional studies are underway.

4. Reduce and inhibit pro-inflammatory cytokines. A topical, nonsteroidal anti-inflammatory agent, benzydamine, has recently been shown to reduce the frequency and severity of oral ulcerations and the associated oral pain in patients with radiation-induced oral ulcers.¹⁹ Benzydamine, in addition to its analgesic and antimicrobial activities, inhibits the production and effects of proinflammatory cytokines.

Treatment

Once mucositis begins, treatment is supportive. Little has been shown to change the overall course of mucositis. General measures such as oral hygiene and dietary modification, topical local anesthetics, and systemic analgesics have been recommended. Other options are currently being studied.

Oral hygiene: Good oral hygiene appears to reduce the severity of oral mucositis. Patients should:

- Brush gently with a soft-bristled toothbrush using fluoride containing toothpaste two or three times daily.

- Floss gently, daily to remove food build-up.
- Rinse the mouth every 4 hours with a dilute saline and baking soda solution (½ teaspoon salt plus ½ teaspoon baking soda in a cup of warm water). Chlorhexidine appears no better than sterile saline. In patients with radiotherapy related mucositis, data suggests that chlorhexidine made them worse.⁵ While this may be soothing, it has not been formally evaluated.
- Remove dentures at night.

Limit food contact: Limit the amount of time food is allowed to come into contact with the oral mucosa. Recommend foods that require little or no chewing. Advise against foods that are irritating, eg, acidic, spicy, salty, coarse, or dry.

Pain relief is challenging. Local anesthetics provide some pain relief. Systemic analgesics are frequently used. Patient-controlled analgesia with an opioid is recommended.¹³ Follow standard opioid dosing guidelines (see EPEC-O Module 2: Cancer Pain Management).

Summary

Mucositis is a mucosal barrier injury, characterized by oral erythema, ulceration, and pain. Its pathobiology is a multiphase process that has only recently been described. Preventive approaches include: diminish mucosal delivery of anti-cancer agents, antimicrobial/anti-inflammatory interventions, modification of the underlying pathobiology, and reduction/inhibition of pro-inflammatory cytokines. Once mucositis is present, treatment focuses on good oral hygiene and comfort measures.

Key take-home points

1. Understanding the pathobiology of mucositis provides the opportunity to develop pathogenesis-based therapies.
2. Mucositis is a debilitating toxicity of treatment.
3. Chemotherapy produces an acute injury while the mucosal injury from radiation therapy tends to be chronic.
4. New agents for prevention are under evaluation.
5. Management focuses on symptomatic relief.

Pearls

1. To differentiate viral ulcers from treatment-induced mucositis, note that viral ulcers typically are localized and involve keratinized mucosa.
2. Oral ulcers secondary to graft versus host disease may occur after hematologic recovery.

3. Provide adequate analgesia!

Pitfall

1. Recent evidence suggests that some of the old mouthwash mixes were actually harmful when compared in head-to-head trials. Don't use them.

34 patients were treated with r-metHuG-CSF. The incidence of febrile neutropenia (absolute neutrophil count <0.5 x 10⁹/L and oral temperature > or = 38.5 degrees C) was 17% in children receiving r-metHuG-CSF, as compared with 40% in the control group (P = .007). Mucositis was also reduced.

Oral cooling is a cheap and available method to lower the severity of bolus 5-fluorouracil-induced oral mucositis. Results of studies with granulocyte-macrophage colony-stimulating factor or granulocyte colony-stimulating factor are promising. Modification of the chemotherapy regimen resulting in shortening of the exposition time to chemotherapy agents or chronomodulation of chemotherapy has been shown to lower mucosal toxicity of some regimens. No agent has been shown to be uniformly efficacious and can be accepted as standard therapy of chemotherapy- and radiotherapy-induced oral mucositis.
